3.542 to 3.600 GeV collected in 2012 for a fully used in our previous measurement of the number of collected in 2009 and four energy points ranging from the standard model. The number of $N_{\psi(3686)}$ in 2012, the BESIII experiment accumulated the world's largest $\psi(3686)$ data sample produced in electron-positron collisions, which provides an excellent resource to precisely study $\psi(3686)$ transitions and decays and those of daughter charmonium states, e.g., $\chi_{cJ}, h_{c}$, and $\eta_{c}$, as well as to search for rare decays for physics beyond the standard model. The number of $\psi(3686)$ events, $N_{\psi(3686)}$, is a crucial parameter, and its precision will directly affect the accuracy of these measurements.

In this paper, we present the determination of $N_{\psi(3686)}$ using inclusive $\psi(3686)$ hadronic decays, whose branching fraction is known rather precisely, $(97.85\pm 0.13)\%$ [1]. In the analysis, the QED background yield under the $\psi(3686)$ peak is evaluated by analyzing the two sets of off-resonance data taken close in time with the peak samples, i.e., center-of-mass energy $\sqrt{s}=3.65$ GeV collected in 2009 and four energy points ranging from 3.542 to 3.600 GeV collected in 2012 for a $\tau$-mass scan. The strategy for the background estimation was successfully used in our previous measurement of the number of $\psi(3686)$ events collected in 2009 [2].
The BESIII detector is modeled with a MC simulation based on GEANT4 [6]. The $\psi(3686)$ produced in the electron-positron collisions are simulated with the generator KKMC [7], which includes the beam energy spread according to the measurement of BEPCII and the effect of initial state radiation (ISR). The known decay modes of $\psi(3686)$ are generated with EVTGEN [8] according to the branching fractions in the Particle Data Group, PDG [1], while the remaining unknown decays are simulated using the LUNDCHARM model [9]. The MC events are generated with mixing of randomly triggered events (non-physical events from collision) in data taking to take into account the possible effects from beam-related backgrounds, cosmic rays, and electronic noise.

3 Event selection

The data collected at the $\psi(3686)$ peak includes several different processes, i.e., $\psi(3686)$ decays to hadrons or lepton pairs ($e^+e^-, \mu^+\mu^-$, and $\tau^+\tau^-$), radiative return to the $J/\psi$, $J/\psi$ decay due to the extended tail of the $J/\psi$ line shape, and non-resonant (QED) processes, namely continuum background, including $e^+e^-\rightarrow\gamma\rightarrow$ hadrons, lepton pairs, and $e^+e^-\rightarrow e^+e^-+X$ ($X=$hadrons, lepton pairs). The data also contains non-collision events, e.g. cosmic rays, beam-associated backgrounds, and electronic noise. The process of interest in this analysis is $\psi(3686)$ decaying into hadrons.

Event selection includes track and photon level selection and event level selection. Charged tracks are required to be within 1 cm of the beam line in the plane perpendicular to the beam and within ±10 cm from the Interaction Point (IP) in the beam direction. Showers reconstructed in the EMC barrel region (|cos$\theta$| < 0.80) must have a minimum energy of 25 MeV, while those in the end-caps (0.86 < |cos$\theta$| < 0.92) must have at least 50 MeV. The photons in the polar angle range between the barrel and end-caps are excluded due to the poor resolution. A requirement of the EMC cluster timing [0, 700] ns is applied to suppress electronic noise and energy deposits unrelated to the event.

At least one charged track is required for each candidate event. In the following, the selected events are classified into three categories according to the multiplicity of good charged tracks, i.e., $N_{\text{good}}=1$, $N_{\text{good}}=2$, and $N_{\text{good}}>2$, and named type-I, II, and III, respectively.

For type-III events, no further selection criteria are required. For type-II events, the momentum of each track is required to be less than 1.7 GeV/c and the opening angle ($\Delta_\phi$) between the two charged tracks is required to be less than 176° to suppress Bhabha and dimuon backgrounds. Figures 1 and 2 show the scatter plots of the momentum of the first charged track versus that of the second charged track, and the distribution of the opening angle between the two charged tracks for the type-II candidates from simulated Bhabha (top) and inclusive $\psi(3686)$ (bottom) MC events, respectively. Further, an energy fraction requirement $E_{\text{visible}}/E_{\text{cm}}>0.4$ is applied to suppress the low energy background (LEB), comprised mostly of $e^+e^\rightarrow e^+e^-+X$ and double ISR events ($e^+e^-\rightarrow \gamma_{\text{ISR}}\gamma_{\text{ISR}}X$). Here, $E_{\text{visible}}$ is the visible energy which is defined as the total energy of all charged tracks (calculated with the track momentum assuming the tracks to be pions) and neutral showers, and $E_{\text{cm}}$ is the center-of-mass energy. Figure 3 (top) shows the $E_{\text{visible}}/E_{\text{cm}}$ distributions of the type-II events for the $\psi(3686)$ data and inclusive MC sample. The visible excess in data at low energy is from the LEB events. Unless noted, in all plots, the points with error bars are the $\psi(3686)$ data collected in 2012, and the histogram is the corresponding MC simulation.

---

![scatter_plots](image.png)
Fig. 2. (color online) Distributions of the opening angle between the two charged tracks for the type-II candidates from (top) Bhabha and (bottom) inclusive $\Psi(3686)$ MC events after applying the momentum requirement for two tracks ($P < 1.7$ GeV/c). The arrow shows the angle requirement used to suppress Bhabha and dimuon events.

For type-I events, at least two photons are required in an event. Compared to those events with high charged track multiplicity, the type-I sample has more background according to the vertex distribution of the charged tracks. Thus, a neutral hadron $\pi^0$ candidate is required to suppress the background events [10], where the $\pi^0$ candidate is reconstructed by any $\gamma\gamma$ combination. In an event, only the $\pi^0$ candidate with a mass closest to $\pi^0$ nominal value and satisfying $|M_{\gamma\gamma} - M_{\pi^0}| < 0.015$ MeV$/c^2$ is kept for further analysis. Figure 4 shows the $M_{\gamma\gamma}$ distribution of selected $\pi^0$ candidates for type-I events. With the above selection criteria, the corresponding $E_{\text{visible}}/E_{\text{cm}}$ distributions of the candidate events for the $\Psi(3686)$ data and inclusive MC sample are shown in Fig. 3 (bottom). An additional requirement $E_{\text{visible}}/E_{\text{cm}} > 0.4$ is used to suppress the LEB events.

To discriminate the non-collision background from the collision events, the average vertex position in the $Z$ direction is defined:

$$V_Z = \frac{\sum_{i=1}^{N_{\text{good}}} V_Z^i}{N_{\text{good}},}$$

where $V_Z^i$ is the (signed) distance along the beam direction between the point of closest approach of the $i^{th}$ track and the IP. The $V_Z$ distributions of the accepted hadronic events for the $\Psi(3686)$ and off-resonance data are shown in the top and bottom plots of Fig. 5, respectively. The events satisfying $|V_Z| < 4$ cm are taken as signal, while the events in the sideband region $6 < |V_Z| < 10$ cm are taken as non-collision background events. The number of the observed hadronic events ($N_{\text{obs}}$) is obtained by counting the events in the signal region ($N_{\text{signal}}$) and subtracting the non-collision background contribution estimated from the events in the sideband regions ($N_{\text{sideband}}$) [11].

$$N_{\text{obs}} = N_{\text{signal}} - N_{\text{sideband}}.$$  

We also determine the number of hadronic events by fitting the $V_Z$ distribution, where the signal event shape is described with a double Gaussian function, and the non-collision background is described with a second-order polynomial function. The resultant fit curves are shown in Fig. 5. This approach is used as a cross check and to estimate the corresponding systematic uncertainty.

Fig. 3. (color online) Distribution of $E_{\text{visible}}/E_{\text{cm}}$ for the (top) type-II and (bottom) type-I events. The MC distributions are scaled to have the same number of entries as data for $E_{\text{visible}}/E_{\text{cm}} > 0.4$. 

023001-5
where $\mathcal{L}$ is the integrated luminosity, $\sigma$ is the theoretical cross section for the QED processes, and $\epsilon$ is the efficiency determined from a MC simulation. Alternatively, as mentioned in Section 1, the off-resonance data samples can be used to estimate the continuum QED background yield. We apply the same approach to determine the yields of collision events and their uncertainties for the off-resonance data samples, which are dominated from the continuum QED processes. With the above method, the effect of QED background is independent of the MC simulation and the corresponding systematic bias is expected to be small.

For the $\psi(3686)$ and off-resonance data samples, the backgrounds from the radiative return to the $J/\psi$ and $J/\psi$ decay due to the extended tail are very similar due to the small difference in the center-of-mass energies. The total cross sections for these two processes are estimated to be 1.11 nb and 1.03 nb at the $\psi(3686)$ peak and the off-resonance energy point, respectively [12]. Detailed MC studies show that the efficiencies for the continuum processes are equal at these two energy points. Therefore, the off-resonance data can be employed to subtract both the continuum QED and $J/\psi$ decay backgrounds using a scaling factor, $f$, determined from the integrated luminosity multiplied by a factor of $\frac{1}{s}$ to account for the energy dependence of the cross section,

$$f = \frac{\mathcal{L}_{\psi(3686)}}{\mathcal{L}_{\text{off-resonance}}},$$

where $\mathcal{L}_{\psi(3686)}$ and $\mathcal{L}_{\text{off-resonance}}$ are the integrated luminosities for the $\psi(3686)$ and off-resonance data samples, respectively, and $s_{\psi(3686)}$ and $s_{\text{off-resonance}}$ are the corresponding square of center-of-mass energies. For the $\tau$-scan data, the average energy is determined to be $\sqrt{s} = 3.572$ GeV. The scaling factors $f$ are determined to be 3.61 and 20.56 for the 2009 and 2012 data samples, respectively.

The integrated luminosities of the data samples taken at different energy points are determined from $e^+e^-\to \gamma\gamma$ events using the following selection criteria. Each event is required to have no good charged tracks and at least two showers. The energies for the two most energetic showers must be higher than 1.6 GeV, and the cosine of the polar angle of each electromagnetic shower must be within the region $|\cos \theta| < 0.8$. The two most energetic showers in the $\psi(3686)$ rest frame must be back to back with azimuthal angles $|\phi_1 - \phi_2| < 180^\circ < 0.8^\circ$. The luminosities are $161.63 \pm 0.13$ pb$^{-1}$ and $506.92 \pm 0.23$ pb$^{-1}$ for $\psi(3686)$ data taken during 2009 and 2012, respectively, while $43.88 \pm 0.07$ pb$^{-1}$ and $23.14 \pm 0.05$ pb$^{-1}$ for off-resonance data taken at $\sqrt{s} = 3.65$ GeV and for the $\tau$-scan data set [13], respectively. Here, the errors are statistical only. The systematic uncertainties related to the luminosity almost cancel in calculating the scaling

$$N^{\text{QED}} = \mathcal{L} \cdot \sigma \cdot \epsilon,$$
factor due to the small difference between the energy points.

\[ \frac{E_{\text{visible}}}{E_{\text{cm}}} \]

Fig. 6. (color online) Comparison of the \( E_{\text{visible}}/E_{\text{cm}} \) distributions for the (top) type-I and (bottom) type-II LEB events between the \( \psi(3686) \) and scaled off-resonance data. The dots with error bars are the former, and the shaded histogram is the latter.

In order to show that the shape of the LEB events in off-resonance data is consistent with that in the \( \psi(3686) \) sample, and, therefore, scaled off-resonance data can be used to remove LEB background in the \( \psi(3686) \) sample, we select an LEB sample by requiring \( E_{\text{visible}}/E_{\text{cm}} < 0.35 \), where few QED events are expected. Figure 6 (top and bottom) shows the comparisons of the \( E_{\text{visible}}/E_{\text{cm}} \) distributions for the type-I (top) and type-II (bottom) LEB events between the \( \psi(3686) \) and the scaled off-resonance data samples taken in 2012. The ratios of the number of events between the \( \psi(3686) \) peak and the off-resonance energy are 22.78 and 22.57 for the type-I and type-II events, respectively. Compared with the scaling factor obtained from the integrated luminosity normalization in Eq. (3), a difference of 10% is found for the type-I and type-II events. Similar differences are found for the 2009 data sample [2]. Since the fraction of LEB events in the selected sample is very small, the effect of this difference for the background estimation is negligible.

The cross sections for \( e^+e^- \rightarrow \tau^+\tau^- \) are 0.67, 1.84, and 2.14 nb at the \( \tau \)-scan energy (\( \sqrt{s}=3.572 \) GeV according to luminosity weighted average), \( \sqrt{s}=3.65 \) GeV and the \( \psi(3686) \) peak, respectively. Since the above energy points are close to \( \tau^+\tau^- \) mass threshold, the production cross section does not follow a \( 1/s \) distribution. Thus, only a part of the \( e^+e^- \rightarrow \tau^+\tau^- \) background events is included in the off-resonance data samples. To correct for the full background from \( e^+e^- \rightarrow \tau^+\tau^- \), we estimate the remaining contribution, \( N_{\text{uncanceled}}^{\tau^+\tau^-} \), using the detection efficiency from MC simulation and the cross section difference at off-resonance energy points and the \( \psi(3686) \) peak, as well as the luminosity at the \( \psi(3686) \) peak. The estimated values are shown in Table 1.

The small numbers of surviving events from \( \psi(3686) \rightarrow e^+e^-, \mu^+\mu^- \), and \( \tau^+\tau^- \) in data do not need to be explicitly subtracted since these leptonic \( \psi(3686) \) decays have been included in the inclusive MC samples, and their effects are considered in the detection efficiency.

### Table 1. Numbers of the observed hadronic events, \( N_{\text{obs}}^{\psi(3686)}(\times 10^6) \), numbers of the observed hadronic events in off-resonance data, \( N_{\text{of}r-\text{res}}(\times 10^6) \), corresponding to the bottom plot in Fig. 5, numbers of the remaining \( e^+e^- \rightarrow \tau^+\tau^- \) events after subtracting the normalized off-resonance data, \( N_{\text{uncanceled}}^{\tau^+\tau^-}(\times 10^6) \), the detection efficiencies, \( \epsilon \), of \( \psi(3686) \rightarrow \text{hadrons} \) for different charged-track multiplicity requirements, and numbers of \( \psi(3686) \) events, \( N_{\psi(3686)} \) (\( \times 10^6 \)).

Fig. 7. (color online) Comparisons of data and MC simulation: (top-left) The $\cos \theta$ distribution, (top-right) $E_{\text{visible}}/E_{\text{cm}}$ distribution, (bottom-left) charged-track multiplicity distribution, and (bottom-right) photon multiplicity distribution.

Table 1 also shows the numbers of the observed hadronic events for different charged-track multiplicity requirements of the $\psi(3686)$ ($N_{\text{obs}}^{(3686)}$) and off-resonance data ($N_{\text{obs}}^{\text{off-resonance}}$). The corresponding detection efficiencies of $\psi(3686) \rightarrow$ hadrons are determined with $363.7 \times 10^6 \psi(3686)$ inclusive MC events, and are also listed in this table. The branching fraction of $\psi(3686) \rightarrow$ hadrons is included in the efficiency. Figure 7 shows the comparisons for $\cos \theta$, $E_{\text{visible}}/E_{\text{cm}}$, charged-track multiplicity, and photon multiplicity distributions after background subtraction between data and MC simulation, and reasonable agreement between data and MC simulation is observed.

5 Numerical results

The number of $\psi(3686)$ events, $N_{\psi(3686)}$, can be calculated from

$$N_{\psi(3686)} = \frac{N_{\text{obs}}^{\text{peak}} - f \cdot N_{\text{obs}}^{\text{off-resonance}} - N_{\text{uncanceled}}}{\epsilon}. \quad (4)$$

With the numbers listed in Table 1, the numerical results for $N_{\psi(3686)}$ with different charged-track multiplicity requirements are calculated and listed in Table 1. There are slight differences between different multiplicity requirements due to the imperfect MC simulation of the charged track multiplicity. To obtain a more exact numerical result for $N_{\psi(3686)}$, an unfolding method is employed based on an efficiency matrix, whose matrix elements, $\epsilon_{ij}$, represent the probability to observe $i$ charged tracks for an event with $j$ actual charged tracks. The efficiency matrix is determined from the inclusive MC samples. In practice, there are even numbers of charged tracks generated in an event due to charge conservation, while any number of charged tracks can be observed due to the reconstruction efficiency and backgrounds. Therefore, the true charged track multiplicity of the data sample is estimated from the observed multiplicity and the efficiency matrix by minimizing a $\chi^2$ value, defined as

$$\chi^2 = \sum_{i=1}^{10} \left( \frac{N_{\text{obs}}^i - \sum_{j=0}^{10} \epsilon_{ij} \cdot N_j}{N_{\text{obs}}^i} \right)^2, \quad (5)$$

where the values $N_{\text{obs}}^i (i = 0, 1, 2, \cdots)$ are the observed multiplicities of charged tracks in data sample which correspond to the distribution in Fig. 7 (bottom-left, the points with error bars), while the values $N_j (j = 0, 2, 4, \cdots)$ are the true multiplicities of charged tracks in the data sample. They are the free parameters in the fit. For simplicity, the events with ten or more tracks are combined in a single value, $N_{10}$. The value of $N_{\psi(3686)}$ can be calculated by summing over all the obtained $N_j$. The results are $107.0 \times 10^6$ and $341.1 \times 10^6$ for the 2009
and 2012 data samples, respectively.

6 Systematic uncertainties

The systematic uncertainties in the \( N_{\psi(3686)} \) measurement from different sources are described below and listed in Table 2. The total systematic uncertainty is determined by the quadratic sum of all individual values.

6.1 Polar angle

The polar angle acceptance for the charged tracks in the MDC is \(|\cos \theta| < 0.93\). From Fig. 7 (top-left), there is a slight difference between data and MC simulation at large polar angles. As a check, the requirement on the polar angle is changed to be \(|\cos \theta| < 0.8\). The difference in \( N_{\psi(3686)} \) is taken as the uncertainty due to the requirement on the polar angle.

6.2 Tracking

A small difference (less than 1%) on the tracking efficiency between data and MC simulation is observed by various studies [14]. Assuming the average efficiency difference between data and MC simulation is 1% per track, the effect can be determined by randomly removing MC simulated tracks with a 1% probability. This results in a negligible difference in \( N_{\psi(3686)} \), implying that \( N_{\psi(3686)} \) is not sensitive to the tracking efficiency.

6.3 Charged-track multiplicity

The effect due to the simulation of the charged-track multiplicity has been taken into account by the unfolding method described above. By comparing the results between the direct calculation in Table 1 and the unfolding method including the \( N_{\text{good}} \leq 1 \) events, there is a difference of 0.2% on \( N_{\psi(3686)} \) for both the 2009 and 2012 data, which is taken as the uncertainty associated with the charged-track multiplicity.

6.4 Momentum and opening angle

For the type-II events, the requirements on the momentum of charged tracks and the opening angle between two charged tracks are applied to reject the sizable background from Bhabha and dimuon events. When the requirement of charged track momentum is changed from \( P < 1.7 \) GeV/c to \( P < 1.55 \) GeV/c, the resultant change in \( N_{\psi(3686)} \) is negligible. When the requirement on opening angle between two charged tracks is changed from \( \theta < 176^\circ \) to \( \theta < 160^\circ \), the change in \( N_{\psi(3686)} \) is negligibly small for the 2009 data and is 0.04% for the 2012 data. Figure 8 shows comparisons of the distributions of the momentum and the opening angle of the two charged tracks after background subtraction in the type-II events between the data and inclusive MC simulation.

6.5 LEB contamination

\( N_{\psi(3686)} \) is insensitive to the visible energy requirement. The uncertainty associated with the requirement \( E_{\text{visible}}/E_{\text{cm}} > 0.4 \) is estimated by comparing the results with or without this requirement, and the difference on \( N_{\psi(3686)} \) is assigned to be the corresponding uncertainty.

6.6 Determination of \( N_{\text{obs}} \)

As mentioned as in Sec. 3, two methods are used to obtain \( N_{\text{obs}} \). The nominal method counts the numbers of events in the signal region and subtracts the number of background estimated in the sideband regions. The alternative method is performed by fitting the \( \hat{V}_{Z} \) distribution. The resultant difference on \( N_{\text{obs}} \) between these two methods is taken as the uncertainty in the determination of \( N_{\text{obs}} \).

6.7 Vertex requirement

We repeat the analysis by changing the requirement \( V_z < 1 \) cm to \( V_z < 2 \) cm, and the change in \( N_{\psi(3686)} \) is small and is taken as the systematic uncertainty. Similarly, we repeat the analysis by changing the requirement \(|\hat{V}_{Z}| < 10\) cm to \(|\hat{V}_{Z}| < 20\) cm, and find a negligible change in \( N_{\psi(3686)} \).
6.8 Scaling factor

The scaling factor ($f$) for the background subtraction depends on the luminosity of the data samples. In the nominal analysis, the luminosity is estimated with $e^+e^- \rightarrow \gamma\gamma$ events. An alternative measurement of the luminosity is performed with large angle Bhabha events, and the scaling factor as well as $N_{\psi(3686)}$ are recalculated. The resultant difference in $N_{\psi(3686)}$ is found to be negligible, and the corresponding uncertainty is negligible.

6.9 Choice of sideband region

In the nominal analysis, we take $|\vec{V}_Z|<4$ cm as the signal region and $6<|\vec{V}_Z|<10$ cm as the sideband region. An alternative analysis is done shifting the sideband region outward by 1 cm, which is about 1$\sigma$ of the $\vec{V}_Z$ resolution. The resulting difference in $N_{\psi(3686)}$ is taken as the systematic uncertainty.

6.10 $\pi^0$ mass requirement

The $\pi^0$ mass requirement is only applied for the type-I events. There is a slight change in $N_{\psi(3686)}$ when the mass window requirement is changed from $|M_{\gamma\gamma} - M_{\pi^0}|<0.015$ GeV/$c^2$ to $|M_{\gamma\gamma} - M_{\pi^0}|<0.025$ GeV/$c^2$. This difference is taken as the uncertainty due to the $\pi^0$ mass requirement.

6.11 Missing $N_{\text{good}}=0$ hadronic events

A detailed topological analysis is performed for the events with $N_{\text{good}}=0$ in the inclusive MC sample. Most of these events come from the well-known decay channels, such as $\psi(3686) \rightarrow X + J/\psi$ (where $X$ denotes $\eta, \pi^0, \rho^0, \gamma\gamma$ etc.) and $\psi(3686) \rightarrow e^+e^-$, $\mu^+\mu^-$. The fraction of these $N_{\text{good}} = 0$ events in the inclusive MC sample is ~2.0%, of which the pure neutral channels contribute about 1.0%. As shown in Fig. 7, the MC simulation models data well. Therefore, we investigate the pure neutral hadronic events, which are selected according to the following scheme. With the same charged track and shower selection criteria as above, we require $N_{\text{good}}=0$ and $N_s > 3$. The latter requirement is used to suppress $e^+e^- \rightarrow \gamma\gamma$ and beam-associated background events. The same selection criteria are imposed on the off-resonance data and inclusive MC events. Figure 9 shows the distributions of the total energies in the EMC, $E_{\text{EMC}}$, for the different data sets and inclusive MC sample. The peaking events around the center-of-mass energy are taken as the pure neutral hadronic candidates. As shown in Fig. 9, the number of signal events is determined by a fit of the $E_{\text{EMC}}$ distribution. In this fit, the signal is described by a Crystal Ball function, the QED background in $\psi(3686)$ data is described by the shape of off-resonance data (off-resonance data at $\sqrt{s}=3.65$ GeV or $\tau$-scan data) after scaling for luminosity, and the other backgrounds are described by a polynomial function. For the 2012 data, the difference in the number of pure neutral hadronic events between the data and the inclusive MC simulation sample is 11% if the $\tau$-scan data sample is taken as the off-resonance data to estimate the background function, as shown in Fig. 9 (top). However, this difference changes to 18% if we use the off-resonance data at $\sqrt{s}=3.65$ GeV for the background function, as shown in Fig. 9 (middle). The larger difference is used to estimate the uncertainty conservatively. Since the fraction

![Fig. 9](image_url)
of the pure neutral hadronic events is about 1.0% of the total selected candidates, the uncertainty due to the missing $N_{\text{good}}=0$ events should be less than $18\% \times 1\% = 0.18\%$ for the 2012 data. The same method is applied to the 2009 data samples, and the uncertainty is 0.25%, which is somewhat larger than the previous analysis [2].

6.12 MC modeling

The uncertainty due to the MC simulation of inclusive $\Phi(3686)$ decays arises from sources such as the input of branching fractions, the angular distributions of the known and unknown decay modes, etc. These uncertainties have been covered by those from the charged-track multiplicity, missing of $N_{\text{good}}=0$ events etc. Thus, no further uncertainty is assigned for the MC modeling.

6.13 Trigger

Based on the 2009 data, the trigger efficiency for the $N_{\text{good}} \geq 2$ (type-II and type-III) events is close to 100.0%, while it is 98.7% for the type-I events [15]. Since the fraction of type-I events is only about 3% of the total selected events, the uncertainty caused by the trigger is negligible for the 2009 data. As shown in Table 1, the fraction of type-I events in the 2012 data is the same as that in the 2009 data. Furthermore, an additional neutral trigger channel was added during 2012 data taking. Therefore, the trigger efficiency for the 2012 data is expected to be higher for type-I events than that for the 2009 data, and the uncertainty associated with the trigger is negligible.

6.14 $B(\Phi(3686) \to \text{hadrons})$

The uncertainty of the branching fraction for $\Phi(3686) \to \text{hadrons}$ is small, 0.13% [1] and taken as the uncertainty.

7 Summary

The number of $\Phi(3686)$ events taken by BESIII in 2012 is measured to be $(341.1 \pm 2.1) \times 10^6$ with the inclusive hadronic events, where the uncertainty is systematic and the statistical uncertainty is negligible. The number of $\Phi(3686)$ events taken in 2009 is also updated to be $(107.0 \pm 0.8) \times 10^6$, which is consistent within the uncertainty with respect to the previous measurement, and the improved precision is due to the refined offline software, MC tuning, and the improved method to determine $N_{\Phi(3686)}$. Adding the results linearly yields the total number of $\Phi(3686)$ events for the two runs to be $(448.1 \pm 2.9) \times 10^6$. This work provides an important parameter for the studies of the decays of the $\Phi(3686)$ and its daughters.

The BESIII collaboration thanks the staff of BEPCII and the computing center for their hard efforts.
